

Type inference for PHP

The value of annotations in a dynamic language

Abstract

Dynamic language are generally hard to statically analyse because of run-time dependencies. Without running the program there are many things unknown. Because dynamic languages are PHP are widely used, the need for decent analysis tool grows. This research examines the value of adding annotations to PHP code to improve the analysability. In the results we see that annotations improve the analysability of software code (this is a guess). Here I should state something about the correctness of the annotations. And end with a general conclusion.

Preface

In this section I will thank everyone who has helped me. Maybe also introduce some anecdote on how this research came to be.

Chapter 1

Introduction

1.1 PHP

PHP¹ is a server-side programming language created by Rasmus Lerdorf in 1995. The original name ‘Personal Home Page’ changed to ‘PHP: Hypertext Preprocessor’ in 1998. PHP source files are executed using the PHP Interpreter. The language is dynamically typed, the types of variables are examined during run-time. In statically typed languages all variable types are known at compile time. PHP supports duck-typing, which allows variables to change types during execution.

Evolution The programming language PHP evolved after its creation in 1995. In the year 2000 Object-Oriented (OO) language structures were added to the language with the release of PHP 4.0. The 5th version of PHP was released in 2004 and provided an improved OO structure. Namespaces were added in PHP 5.3 in 2009, to be able to resolve class naming conflicts between library and create better readable class names. Namespaces are comparable to packages in Java. OPcache extension is added was added in PHP 5.5 and speeds up the performance of including files on run-time by storing precompiled script byte-code in shared memory. The most recent stable version is 5.6 and includes more internal performance optimisations and introduces a new debugger.

Popularity According to the Tiobe Index² of December 2014, PHP is the 6th most popular language of all programming languages. The language has been in the top 10 since its introduction in the Tiobe Index in 2001. More than 80 percent of the websites have a php backend³. The majority of these websites use PHP version 5, rather than version 4 or older versions. It is therefore wise to focus on PHP version from 5 and discard the older unused versions.

Analysability Although the popularity for more than a decade, there is still a lack of good PHP code analysis tools. Tools can help to reveal security vulnerabilities or find vulnerabilities or bugs in source code. The tools can also provide code completions or do automatic transformations which can be used to execute refactoring patterns. Source code analysis can be performed statically or dynamically or a combination of the two. More information on the analysability of php can be found in section 2.1.

1.2 Position

In this research we investigate how we can improve the analysability of PHP programs. We will show that the use of annotated source code can help to improve the analysability. The correctness of the annotations can also be examined by checking the implementation of the code. These annotations can help to improve the analysis. The results can be used to find security issues, and if they are highly reliable we can even make compiler optimisations.

²<http://www.tiobe.com/index.php/content/paperinfo/tpci/index.html>, December 2014

³<http://w3techs.com/technologies/details/pl-php/all/all>, December 2014

As far as we know, there is no constraint based type inference research like this one performed for PHP. That makes this research unique. There have been similar analysis for other dynamic languages, like smalltalk, ruby and javascript, but none like this.

1.3 Contribution

TODO Review this part when the result of the analysis are performed.

- Created an M3 for php.
- Constraint system.
- Show the value of annotations for analysis.

Some idea's are that this analysis can help IDE tools to perform transformations on the source code. (But the performance may not be sufficient.)

The creation of the M3 model can help to compare researchers compare PHP programs with other programming languages. For now only Java is implemented, but more can follow (unchecked statement).

1.4 Plan

The rest of this thesis is as follows: chapter 2 contains background and related work. Background exists of important language constructs, information about annotations in PHP, introduction to M^3 and type systems. The last section of this chapter shows similar research and their relation to this research. Chapter 3, research method, defines the research question and the research context. Chapter 4 describes the performed actions of this research. The analysis is presented in chapter 5, with the results in chapter 6. This thesis ends with the conclusions in chapter 8.

Chapter 2

Background and Related Work

Chapter 2 describes seven important language constructs which the reader needs to understand in order to understand the difficulties of analysing PHP in section 2.1. The second section, section 2.2, introduces the syntax and usage of annotations in PHP. Section 2.3 explains *Rascal*, the programming language used for the analysis. In this section we will explain M^3 , a programming language independent meta model which holds various facts about programs, in more details. Section 2.4 introduces type systems and how type systems relate to this research. The last section of this chapter, section 2.5, describes the related work and how these researches are related to this thesis.

2.1 PHP Language Constructs

PHP has various language constructs which complicate statical analysis. This section presents language constructs and why these constructs are important for this research. Explanations of these constructs help you to understand the performed analysis. The discussed parts are scope, file includes, conditional classes and functions, dynamic features, late static binding, magic methods and dynamic class properties.

Scope In PHP, all classes and functions are globally accessible once they are declared. All classes and functions are implicitly public, inner classes are not allowed, and conditional functions (see paragraph about conditional classes and functions) will be available in the global scope. If a class or function is declared inside a namespace, their name is prefixed with the name of the namespace.

Variables have three scope levels: global-, function-, and method-scope. Under normal circumstances when a variable is declared inside a function or method, their scope is limited to this function or method. Variables declared outside function or methods are available in the global scope, but not in the method or function scope. There is an exception for some predefined global variables which are available everywhere. Examples are `$GLOBALS`, `$_POST`, and `$_GET`. Variables inside a function or method can be aliased to a global variable by adding the keyword `GLOBAL` in front of the variable name. The variable are then linked to the global variable in the symbol table¹.

Closures (anonymous functions in PHP) have the same scoping rules as variables, but they can inherit variables from outside their scope by providing them in the use statement.

Includes PHP allows files to include other PHP-files during execution of the program. The content of these files will be loaded inline. This means that if you use an include in the middle of a file, the source code of this file will be inserted virtually at that place. In this research we will not perform an include analysis. Instead we will assume that all files in the project are included during execution.

According to the php coding standard², function- and class-name classes should not appear when using namespaces and autoloading. When a class which is not already loaded in memory, the autoloading function will try to include a file and load the class. The structure of the autoloading is meant to include classes, interfaces, traits, and functions and should not have inline code executions which would lead to side-effects.

¹<http://php.net/manual/en/language.variables.scope.php>, July 2014

²<http://www.php-fig.org/psr/psr-0/>, July 2014

Conditional classes and functions Once a file is included in the execution, all the classes and functions in the top scope are declared. All class and function declarations within condition statements or within a method or function scope are only declared when the code is executed.

An example of an conditional statement can be found in listing 2.1. If the class `Foo` or function `bar` do not exist before the statements is executed, then the class and function will not yet be declared. When you try to use the class or function before the code is executed, the script will exit with a fatal error.

```
1 if (!class_exists("Foo"))
2     class Foo { /* ... */ }
3
4 if (!function_exists("bar"))
5     function bar() { /* ... */ }
```

Listing 2.1: Conditional class and function definitions

More examples of dynamic function and class loading is displayed in listing 2.2. If the first call is `g()` as you can see in line 8, the script will result in a fatal error because function `g()` will only be declared after function `f()` is executed. The class `C` will be declared once function `g()` is executed. As soon as the functions and classes are declared, they are available in the top scope, possibly prefixed with the name of the namespace they are declared within.

```
1 function f() {
2     function g() {
3         class C {}
4     }
5 }
6
7 // Execution examples:
8 g(); // will fail because 'g();' is not declared yet
9 f(); g(); // will work because 'g();' is declared when calling 'f();'
10 f(); new C(); // will fail because 'g();' needs to be called first
11 f(); g(); new C(); // will work because 'g();' is called and has declared 'f();'
```

Listing 2.2: Conditional function declaration

Dynamic features PHP comes with dynamic features like: include dynamic variables, dynamic class instantiations, dynamic function calls, dynamic function creation, reflection, and eval. These features allow code to change during compile time. New functions and classes can be declared on the fly. Method calls, or even whole pieces of code, can be executed based on variable strings.

A previous study by Mark Hills[HKV13] has shown that most real applications make use of dynamic features. Dynamic features are powerful, but can complicate the static analysis. Additional analysis like constant propagation is needed to resolve most of these dynamic features. This is not in scope for this research.

Late static binding Late static binding³ is implemented in PHP since version 5.3 by adding the keyword `static` to the language. Its usage is similar to the keyword `self`, which refers to the current class. The main difference is that `self` refers to the class where the code is located, while `static` refers to the actual instantiated class. The keyword `self` can be easily resolved while `static` can only be resolved on runtime. For the keyword `self` we will have to refer to the class it's declared in, plus all their descended classes.

Magic methods PHP allows calls and property access on methods and fields that don't exist on a class. Normally a call to a non-existing method or property would result in a fatal error, but with the use of magic methods you can specify the wanted behavior. Listing 2.3 shows an example of the `__call` method. This method is triggered when a non-accessible or non-existing method is called. In this example the code will try to return the value of a private property based on the provided name. The

³<http://php.net/manual/en/language.oop5.late-static-bindings.php>, July 2014

full list of magic methods is `__construct`, `__destruct`, `__call`, `__callStatic`, `__get`, `__set`, `__isset`, `__unset`, `__wakeup`, `__toString`, `__invoke`, `__set_state`, `__clone`, and `__debugInfo`.

```
1 class Car {
2     private $maxSpeed = 210;
3     function __get($name) { return $this->$name; }
4 }
5 var_dump((new Car)->maxSpeed); // 210
6 var_dump((new Car)->numberOfWheels); // NULL
```

Listing 2.3: Magic methods in PHP

Dynamic class properties Although it is a good practice to define your class properties, it is not required to do so in PHP. After instantiating a class it is possible to add properties to classes, even without the implementation of magic methods. In listing 2.4 you can see a code sample of adding a property after instantiation of a class. The access of the non-existing property `nonExistingProperty` will result in a warning, but code execution will continue and will just return `NULL`. The code on line 4 is where the property is written. The object `$c` will have the `nonExistingProperty` publicly available now. But in a new class instantiation, like you can see on line 6, will not have the property there.

```
1 class C {}
2 $c = new C();
3 var_dump($c->nonExistingProperty); // NULL
4 $c->nonExistingProperty = "property now exists";
5 var_dump($c->nonExistingProperty); // string(19) "property now exists"
6 var_dump((new C)->nonExistingProperty); // NULL
```

Listing 2.4: Dynamic class property

2.2 Annotations

Annotations are pieces of meta data, defined on class, method, function, or statement level. Despite the proposal⁴ for official support of annotations, PHP has still no native support them. But PHP has a `getDocComment`⁵ method in the `ReflectionClass` since version 5.1 in 2005. The `getDocComment` method returns the complete doc block of a certain element as a string. A doc block in php has the format `/**...*/`. Listing 2.5 shows an example of two doc blocks in PHP. The first doc block is defined above the class and contains information about the class. The second doc block is related to the method `getSomething`. The block contains a short description of the method, provides type hints for the parameter and the return type, and provides information which possible exceptions can be thrown by the method.

```
1 namespace Thesis;
2
3 /**
4  * Class Example
5  * @package Thesis
6  */
7 class Example
8 {
9     /**
10      * This is a description of the method getSomething
11      *
12      * @param SomeTypeHint $someObject
13      * @return string
14      * @throws NoNameException
15      */
```

⁴<https://wiki.php.net/rfc/annotations-in-docblock>

⁵<http://php.net/manual/en/reflectionclass.getdoccomment.php>

```

16 public function getSomething(SomeTypeHint $someObject)
17 {
18     if (null === $someObject->getName()) {
19         throw new NoNameException();
20     }
21
22     return $someObject->getName();
23 }
24 }

```

Listing 2.5: Examples of PHP DocBlocks

Annotations are mainly used for type hinting, documentation, and code execution. Software analysis tools and IDE's can use the type hints to aid understanding code and in finding bugs and security issues. Available tools can generate documentation based on the doc blocks. Programs like Symfony2, ZEND Framework, and Doctrine ORM use annotations for controller routing, templating information, ORM mappings, filters, and validation configuration.

This research focusses on the first type of annotations which can help developers and IDE's to better understand how code behaves within a program. For example a programmer can see what kind of input and output is expected for a method. Doc blocks with annotations can be placed on top of classes, methods, functions, and variables.

A standard on using annotations is not in the PHP Standard Recommendations (PSR) yet, but there is a proposal⁶. For this research we will only focus on the @param, @return, @var, and @inheritDoc annotations. The annotations @return and @param are only useful for functions, class methods, and closures. Type hints are described with @var and can be used on all structures, but mainly occur on variables and class fields.

There is no official standard for the use of annotations, but most projects follow the phpDocumentor⁷ syntax. For this research the following annotations are considered:

$$\text{@return} = \left\{ \begin{array}{ll} \text{@return type,} & \text{unconditionally read @return type.} \end{array} \right. \quad (2.1)$$

$$\text{@param} = \left\{ \begin{array}{ll} \text{@param type \$var,} & \text{if '@param type \$var' occurs at least once.} \\ \text{@param \$var type,} & \text{else if '@param \$var type' occurs at least once.} \\ \text{@param type,} & \text{otherwise try to match '@param type'.} \end{array} \right. \quad (2.2)$$

$$\text{@var} = \left\{ \begin{array}{ll} \text{@var type \$var,} & \text{if '@var type \$var' occurs at least once.} \\ \text{@var \$var type,} & \text{else if '@var \$var type' occurs at least once.} \\ \text{@var type,} & \text{otherwise try to match '@var type'.} \end{array} \right. \quad (2.3)$$

$$\text{type} = \left\{ \begin{array}{ll} \text{type|type,} & \text{if '|' in type.} \\ \text{type,} & \text{otherwise} \end{array} \right. \quad (2.4)$$

2.3 Rascal

Rascal[KSV09] is a meta programming language developed by Centrum Wiskunde & Informatica (CWI). Rascal is designed to analyse, transform and visualise source code. The language is build on top of Java and implements various concepts of existing programming languages. In this research, Rascal is the main programming language. The only part that does not use Rascal is the parser of PHP code. Although this could be easily implemented in Rascal, there was an existing library written in PHP available.

⁶<https://github.com/php-fig/fig-standards/pull/169/files>, July 2014

⁷<http://www.phpdoc.org/>

M^3 [Izm+13] is a model which holds various information of source code and is implemented in Rascal. This model is created to gain insights in the quality of open-source projects. For our research we use the M^3 -model to store facts about the program in a structured way, so we can easily use it at a later stage.

The core element of the M^3 -model contains **containment**, **declarations**, **documentation**, **modifiers**, **names**, **types**, **uses**, **messages**. The **declarations** relation contains class, method, variable- information with their logical name and their real location. The type of the relation are **locations** and represent the logical name of the declaration and will be used in the rest of the M^3 . The **containment** relation has information on what declarations are contained in each other. For example a package can contain a class; a class can contain fields and methods or an inner class; a method can contain variables. The **documentation** relation contains all comments from the source code and its source location. The **modifiers** relation has information on the modifiers of declarations. Modifiers are abstract, final, public, protected, or private. The **names** relation contains a simplified name of the full declarations. The **types** relation has information about the type of the source code elements. The **uses** relation describes what references use an object. For instance when a field of a class is used in some expression, the **uses** relation links the field in the expression to the declaration of the field in the class. And lastly, **messages** contains errors, warnings, and info statements.

2.4 Type systems

Type systems define how a set of rules are applied to types in their context. The system validates the type usage with **type checking**. The process of resolving types is called **type inference**. On one hand the system needs to determine the type of variables, on the other hand it will check the type of the variables.

Type checking Type checking is a mechanism which validates and/or enforces the constraints of a type in their specific context. There is a difference between static type checking and dynamic type checking. **Static type checking** is a process of checking the types based on the source code. The static type checker will ensure that a program is type safe before executing the program, which means that there will occur no type errors during runtime. **Dynamic type checking** performs the type checking during runtime. This means that the program needs to run to gain feedback on the usage of types. PHP is a dynamically typed language, which means that there are no types checked before actually running the program. There are languages, like JAVA, which have use a combination of static and dynamic type checking. The advantage of static type checking is that type errors can be caught early in the development process and allows for compiler optimisations. Dynamic type checking systems have more flexibility and allow dynamic loading of new code.

Type inference Type inference is the process of resolving types of variables and expressions. The inference process is a prerequisite to be able to perform type checking. Being able to infer the type before running the program enables you to optimise code execution by applying compiler optimisations. These optimisation allow performance improvements or can optimise memory usage. In dynamic languages like PHP it can be difficult to resolve the type of a variable or expression without running the program. In statically typed languages, type inference happens at compile time. In the next paragraph we will briefly explain some type inference systems.

The **Hindley-Milner**[Hin69] (HM) type system was found in 1969 by Roger J. Hindley and almost 10 years later rediscovered[Mil78] by Robin Milner. The first implementation was created four years later by PhD student Luis Damas. Damas proved the soundness and completeness of the HM type system with **Algorithm W**[DM82] in the context of the programming language ML. The HM type system deduces the types of the variables to their most abstract type, based on their usage. Type declarations and hints are not necessarily to perform type inference. The type system is used for various functional languages. Haskell for example uses the Hindley-Milner type system as a foundation for the Haskell type system.

Control Flow Analysis[NNH99] (CFA) is concerned with resolving sound approximate run-time values at compile time. CFA is build on top of data flow analysis[ASU86] and tries to resolve the control-flow problem. One of the earlier CFA algorithms was Shivers' 0CFA algorithm[Shi88], a flow-sensitive constraint based algorithm. Shiver then defined k -CFA[Shi91], where the precision of the analysis is increased by taking the context of the expressions into account.

The **Cartesian Product Algorithm**[Age95] (CPA) is a type inference algorithm created by Ole Agesen in 1995. Agesen's work was based on Palsberg and Schwartzbach's **basic type inference algorithm**[PS91]. This basic type inference algorithm derives a set of constraints based on *trace graphs* and solves the constraints using a fix-point algorithm. Agesen extended the basic algorithm with *templates*. These templates are based on control flow and have start and end nodes with their possible in- and outputs. The CPA calculates the possible output types for each template by taking the cartesian product (the set of all possible ordered pairs) of the input types.

2.5 Related work

Due to the big growth of the internet in the last couple of years, with a big market share of PHP programs, there are numerous people who have analysed PHP programs. We will briefly describe a few of them.

Facebook improved the performance of PHP programs with a static compiler, called HipHop Virtual Machine[Zha+12] (HHVM). This static compiler extracts the program into an AST, traverses this AST to collect information, performs pre-optimisations, performs type inference, performs post-optimisations, and lastly generates C++ code. During the pre-optimisations the compiler removes unneeded actions, for example constant inlining, logical-expression simplifications, and dead-code elimination. The type inference process is based on the Hindley-Milner constraint based algorithm[DM82], to infer types of constants, variables, functions parameters, and return types. These new inferred types are then used in the post-optimisation. In the last step the AST is traversed to generate C++ code. Although the compiler does not cover all functions of PHP, it does cover most of the features. The performance benefits on the other hand are significantly better, showing on average 5.5x more efficiency.

PHANTM[KSK10a; KSK10b] (PHp ANalyzer for Type Mismatch) is an open source PHP analyser written in Scala. Because of PHP's dynamic nature, without compiler or interpreter type checking, it is easy to make typing errors that result in unexpected behaviour or in fatal errors. PHANTM performs a hybrid flow-sensitive analysis to find type errors in PHP5. The hybrid analysis combines static and dynamic analysis. A program can be annotated to start a static analysis at a specific point. The analyser collects run-time type information while running the program and then starts the static analysis. PHANTM uses data-flow analysis to infer types. Although PHANTM has proven to be able to find a number of type errors in three different programs, there is a lack of finding errors in object oriented structures. The found errors are found in scalar types.

Describe these:

- PHPLint⁸(uses a different kind of annotations, not the Java like PhpDocs)
- 'Soft typing and analyses on PHP programs'[1], code implementations: <https://github.com/henkerik/typing> and <https://github.com/marcelosousa/soft-typing-PHP5> (created for php4, code for php5, should check this out, might be able to compare results with this)
- 'Design and Implementation of an Ahead-of-Time Compiler for PHP'[Big10] (to check in detail)

Also describe their differences with my research.

⁸<http://www.icosaedro.it/phplint>, July 2014

Chapter 3

Research Method

In this research we will try to answer research questions. Section 3.1 describes the research questions. In section 3.2 we will explain more about types, subtypes and their relationship. Section 3.3 explains in which context the research is executed.

3.1 Research question

The main research question we want to answer is:

Will the use of annotations¹ help to do better static source code analysis?

Subquestions:

- What is the accuracy (recall and precision) of our analysis?
- Are annotations used in programs reliable?

The subquestions are here to support the main question. In the first question we want to measure the precision and recall of this research. With precision we want to measure if the results we have are reliable. With recall we want to have the number of results we were able to reveal.

In the second subquestion we want to know if the annotations conform to the documentation. We will measure this by doing the analysis without using annotations, and see if the results fit the annotations.

3.2 Types

PHP is dynamically typed and allow coercions and duck-typing. Coercion make it possible for variables to hold different types Duck-typing checks the object instead of the class.

```
module lang::php::m3::TypeSymbol

data TypeSymbol
  = \any()      | array(TypeSymbol arrayType)
  | boolean()   | class(loc decl)
  | float()     | integer()
  | null()      | object()
  | resource()  | string()
;
```

¹The annotations are limited to: @param, @return, @var, and @inheritDoc.

3.2.1 PHP types

PHP has a similar class inheritance structure and interface implementation as Java. The main difference is that in PHP all class are **public** and that inner classes are not allowed in PHP.

The basis types in PHP are integers, floats (similar to doubles and reals), booleans, strings, arrays, resources and null. When variables are initialised without a values, they are null. The recourse type is a special one which is not important for this research.

3.2.2 Subtypes

Explain something about subtypes here. For now, only this figure 3.1

Figure 3.1: Subtype hierarchy

The subtype relation of class inheritance is a **reflexive transitive closure** relation. A class extension of class A on class C will define class A as a subtype of class C in our analysis, as you can see in figure 3.2. If a class does not extend another class, it will implicitly extend the **stdClass** class. You can see that this happens with class D in the example. The **stdClass** is represented as the type **object()** in our analysis.

The basic PHP types also contain a subtype relation. Integers are subtypes of floats.

Figure 3.2: Relation of subtypes among classes

3.3 Research context

In order to let our research take place, we need to make sure that some environment variables are constant.

Program Correctness In order to be able to execute this research we will need to assume that the program is correct and works as intended. We will assume that the system contains no bugs. This is needed to be able to say something about the programs we analyse.

File includes In this research we will assume that all file are included during runtime. When a PHP system is constructed of classes with namespaces, the files will be logically loaded using PHP's autoloader. Because most recent systems use namespaces, we will assume that all files are included. For legacy systems, this can influence the results of this research.

Register globals Register globals allows variables to be magically be created from GET and POST values. Since it is discouraged to use this setting, we will assume that all software products have this setting disabled.

PHP Warnings For this research we will ignore all warnings. Warnings do not alter the behaviour of the program. In a normal production environment, the warnings are not shown.

Sensitivity Our analysis is flow-, control-, and context-insensitive. Flow-insensitive means that we do not look at messages between objects, and only look in the body of a method. Control-insensitive means that we ignore all control structures. Examples of control structures are `if`, `else`, and `switch`. Context-insensitive means that we do not look at the order of which code is executed.

Chapter 4

Research

The research is executed in 3 main steps. The first step creates an M^3 model for a PHP program and contains various facts about the program. The creation of an M^3 for PHP is explained in more details in section 4.1. Once the M^3 model is constructed, the second step is to extract constraints from the program using the M^3 model. How and which constraints are extracted is described in section 4.2. In the third step, in section 4.3, the constraints are solved and resolve the types of variables used in the program. The final section 4.4 of this chapter explains how annotations can be included in the process to gain more precise results.

4.1 M^3 for PHP

As explained in section ??, M^3 is a language independent meta model which holds facts about programs. The model can be extended with language specific elements and will be used to query the system for facts about the system. An overview how an M^3 for PHP is build is shown in figure 4.1. Independent M^3 models are build each PHP file in the program. All these individual M^3 's are in the end combined to collect all the facts about a program. This results in one M^3 for the whole program. M^3 's are first created for each file is because it is not defined what the dependencies of a individual file are. There is no main file, and all files can load each other. In this research we assume that all files in a program are loaded when needed using autoloaders or manual includes.

Figure 4.1: M^3 Creation

4.1.1 The algorithm

In order to get a better understanding of the creation of an M^3 for PHP, the algorithm is provided in Algorithm 1. **The input** of the algorithm is all the PHP files of a program, which are all files ending on .php. **The output** is an M^3 with facts about the provided program. The algorithm starts with initialising an empty M^3 collection in line 1 which will be filled with the result of each individual file. In the big loop on line 2 to 13 we iterate over all the PHP files of the program. The first thing that needs to be done is to create an Abstract Syntax Tree (AST) of the program using an external PHP parser¹ which returns an Rascal AST in `parseUsingPhpParserAndReturnRascalAST` on line 3. From this AST we create an

¹<https://github.com/ruudvanderweijde/PHP-Parser>

empty M^3 in `createEmptyM3` on line 4. In order to be able to refer to any source code element, we need to have the declarations of the elements. These elements are extracted in `addDeclarations` on line 5 can be `namespace`, `class`, `interface`, `trait`, `method`, `function`, `variable`, `field`, or `constant`. For all functions we need to add scope information in case functions are declared inside another function or method. In line 6 we add the scope information to all nodes to the AST by visiting the AST. This is needed in order to extract the right facts about the logical containment which is done in line 7. The next three lines (8-10) extract facts about class inheritance and the interface implementations, modifiers, PHP doc blocks, and annotations. Once all the basic information is collected, `calculateUsesFlowInsensitive` on line 11 tries to find the declarations of the used objects, methods, functions and variables. This is flow and context insensitive and only tries to resolve non-dynamic language constructs. The last step of the iterator is to add the constructed M^3 to the M^3 collection. Finally when an M^3 is constructed for all files, all facts of the individual M^3 's are merged into one M^3 model in line 14.

Algorithm 1: PHP program to M^3

Input: PHP files of a program

Output: M^3 for the PHP program

```

1 m3Collection = [];
2 forall the file ∈ program do
3     ast = parseUsingPhpParserAndReturnRascalAST(file);
4     m3 = createEmptyM3(ast);
5     m3 = addDeclarations(m3, ast);
6     ast = addScopeInformation(m3, ast);
7     m3 = addContainment(m3, ast);
8     m3 = addExtendsAndImplements(m3, ast);
9     m3 = addModifiers(m3, ast);
10    m3 = addRawDocBlocksAndAnnotations(m3, ast);
11    m3 = calculateUsesFlowInsensitive(m3, ast);
12    m3Collection += m3;
13 end
14 return projectM3 = composePhpM3(m3Collection);
```

4.1.2 Core elements

The M^3 model has the following core elements: **Declarations**, **Containment**, **Modifiers**, **Extends**, and **Uses**. All these core elements are explained in more detail in the paragraphs below.

Declarations defines the declarations of namespaces, classes, interfaces, traits, methods, functions, and variables and holds the relation between the logical name (which is used to refer to the declaration) and the actual file location (which is the physical place in the file system. For example the logical name of a class can be `|php+class://SomeNameSpace/ClassX|` while the actual location might be `|file:///project/SomeNameSpace/ClassX.php|`.

Containment holds information about what elements logically contain other elements. For example, a property or method is contained in a class and a class is contained in a package. When a function is declared in another function, they are both logically contained in the global namespace (the highest level) because all functions are declared as first class citizens in PHP.

Modifiers element contains information about the modifiers of classes, fields, and methods. Classes can only be `abstract`, fields can be `public`, `private`, or `protected`, and methods can be all of them. Abstract methods can only be declared in abstract classes. Classes are implicitly `public`.

Extends contains information about what classes and interface extend other classes or interfaces. Please note that we do not hold information about which class implements which interface, because that information is contained in the **implements** relation. Interface extensions work just like class extensions.

Uses relation holds information about the usages of certain elements. It is the relation between the usage and the declaration. For example when you instantiate a class, in that case you 'use' that specific class.

4.1.3 PHP specific elements

Because every programming language differs in syntax and semantics, the M^3 model is extensible to provide language specific modeling elements. The following php specific items are added: **Implements**, **TraitUses**, **Parameters**, **Constructors**, **Aliases**, and **Annotations**. These PHP specific modeling elements are described in more detail in the paragraphs below.

Implements holds information on what class implements which interfaces. One class can implement multiple interfaces. Because the information is a relation between the class and the interface, we can easily add multiple interfaces to one class in the model.

TraitUses knows which traits a class uses. Traits are a collection of reusable functions, are defined on class level, and one class can have multiple trait usages. All the methods of a trait are on runtime imported in the class.

Parameters keeps track of the parameters of a method or function. This information is stored to make it easier to resolve the call to a method or function.

Constructors lists all the constructors for classes. This information is needed because it is not always clear what constructor is used, due to legacy PHP4 way of using class constructors. In PHP4 the constructor was defined as a method with the same name as the class. Since PHP5 the language is provided with a magic method `__construct()`, which results in two ways to have constructors, but only one constructor will be called. The PHP4 constructors will be removed in PHP7.

Aliases has a relation between aliases and the actual implementation. For instance the function `class_alias` defines a new name for the same class. This relation is also used to keep track of references.

Annotations contain a relation between a declaration and the annotations that are known. Annotations are defined in the raw doc blocks and are parsed using regular expressions (regex). Regex was in this case easier than parsing because there is no official grammar or standard defined. For this research we only use `@param`, `@var`, `@returns`.

Rascal 1 M^3 definitions in Rascal

```
anno rel[loc decl, loc file] M3@declarations;           // 'decl' is the logical name
anno rel[loc from, loc to] M3@containment;             // 'from' directly contains 'to'
anno rel[loc from, loc to] M3@extends;                 // 'from' extends 'to'
anno rel[loc from, loc to] M3@implements;              // 'from' implements 'to'
anno rel[loc decl, PhpParams params] M3@parameters;    // formal parameters of
functions/methods
anno rel[loc decl, loc to] M3@constructors;            // 'decl' and its constructor 'to'
```

4.2 Fact extraction

Besides the just discussed items of the M^3 model, we need to add more facts to the M^3 model. We extract fact about classes, class-constants, class-fields, methods, functions, and parameters. We store these facts in a relation in Rascal. The left side of the relation contains the class, function, or method.

Other facts that will be used:

```
alias PhpParams = lrel[loc decl, set[loc] typeHints, bool isRequired, bool byRef];
data Annotation = returnType(set[TypeSymbol]) | parameterType(loc var, set[TypeSymbol])
  | varType(loc var, set[TypeSymbol]);

anno rel[loc from, loc to] M3@containment;           // 'from' directly contains 'to'
anno rel[loc from, loc to] M3@extends;              // 'from' extends 'to'
anno rel[loc from, loc to] M3@implements;           // 'from' implements 'to'
anno rel[loc decl, PhpParams params] M3@parameters; // formal parameters of functions/methods
anno rel[loc decl, loc to] M3@constructors;         // 'decl' and its constructor 'to'
anno rel[loc decl, Annotation annotation] M3@annotations; // result of parsed php docs
```

4.2.1 Type extraction

In order to define the subtype relations in class extensions, we will need to declare all existing class types. We can do this in rascal like is done in the example below:

```
visit (system) {
  case c:class(_, _, _, _, _): types += class(c@decl);
}
```

Once all types are defined, we can add the subtype relation. We will need to have the subtype of `int()` and `float()` and the class extensions. You can see that in the code below:

```
public rel[TypeSymbol, TypeSymbol] getSubTypes(M3 m3, System system)
{
  rel[TypeSymbol, TypeSymbol] subtypes
    // add int() as subtype of float()
    = { <\int(), float(> }
    // use the extends relation from M3
    + { <class(c), class(e)> | <c,e> <- m3@extends }
    // add subtype of object for all classes which do not extends a class
    + { <class(c@decl), object(> | 1 <- system, /c:class(n,_,noName(),_,_) <- system[1]
};

  // compute reflexive transitive closure and return the result
  return subtypes*;
}
```

4.2.2 Constraint extraction

The constraints used like defined in the book [PS94]. (based on these rules, we can add constraints to the source code)

Introduction is needed here... for now I will just list the types that I have found. Maybe this needs to be moved to a different chapter.

This is a list of items which are not supported (yet):

- References (in PHP they are symbol table aliases)
 - on expression assignments :: $\$a = \&\b
 - on functions :: $\text{function } \&f() \{ \dots \}$
 - on parameters :: $\text{function } f(\&\$a) \{ \dots \}$
- Variable structures:
 - ~~Variable variables~~ :: $\$\a ;
 - ~~Variable class instantiation~~ :: $\text{new } \$a$;
 - ~~Variable method or function calls~~ :: $\$a()$;
- List assign :: $\text{list}(\$a, \$b) = \text{array}(\text{"one"}, \text{"two"})$; (we can assume that the rhs is of type array, when the program is correct)
- ~~Method or function parameters (including type hints)~~
- ~~Class structures, method calls~~
- ~~Class Constants~~
- ~~The global statement~~ (should be resolved by the usage relation from M3)
- ~~Casts of expressions~~
- Parameters
- ~~Predefined variables~~ ($\$this$, $self$, $parent$, $static$)
- ~~Eval~~ (will not be supported)
- ~~Closures~~ (not used much in production code)
- ~~Traits~~ (not used much in production code)
- ~~Callable~~ (introduced in 5.4 as typehint, not used much in production code)
- ~~Foreach~~ ($\$a$ as ... ($=>$...)) $=>$ $\$a$ is an array or an object;
- ~~return;~~ $=>$ ~~return type is null~~ (is added to the situation when there are no return statements)
- add predefined globals (and their type: $\$[GLOBALS, _SERVER, _GET, _POST, _REQUEST, _COOKIE, _ENV, _SESSION, php_errormsg]$ (all in global scope))
- add magic constants: $__[DIR, FILE, LINE, NAMESPACE, FUNCTION, CLASS, METHOD]__$
- predefined constants: ~~TRUE(b), FALSE(b), NAN(f), INF(f), NULL(n), STDIN(r), STDOUT(r), STDERR(r)~~
- $\text{define}(\text{"name"}, \text{value})$ mixed with constants (?out of scope?)
- ~~keywords: self, parent, static in a class~~ (is included in method and property calls)
- ADD CONSTANTS! RECORD THE TYPE OF THE DEFINED CONSTANTS AND TRY TO READ THEIR TYPE.

Legend

\equiv	=	Equal to (expression)	C	=	A class
$=$	=	Equal to (type)	$\rightarrow c$	=	A class constant
$<:$	=	(lhs) is subTypeOf (rhs)	$\rightarrow p$	=	A class property
E_k	=	An expression	$\rightarrow m$	=	A class method
$[E_k]$	=	Type of some expression	$[m]$	=	(Return) type of a method call
f	=	A function	(A_n)	=	The n'th actual argument
$[f]$	=	(Return) type of a function	(P_n)	=	The n'th formal parameter
$:: c$	=	Static property fetch	th	=	Type hint
$:: m$	=	Static method call	v	=	Default value
$:: p$	=	Static property fetch	Γ	=	The program
Mfs	=	Modifiers

Expressions

Normal assignment

$$\frac{E \equiv (E_1 = E_2)}{[E_2] <: [E_1], [E_1] = [E]}$$

```
1 $a = $b; // [$b] <: [$a], [$a] = [$a=$b]
2 $c = $d = $e; // [$e] <: [$d], [$d] <: [$c],
3           // [$d] = [$d=$e], [$c] = [$c=$d=$e]
```

Listing 4.1: Normal assignment

Ternary

$$\frac{E \equiv (E_1 ? E_2 : E_3)}{[E] <: [E_2] \vee [E] <: [E_3]}$$

$$\frac{E \equiv (E_1 ? : E_3)}{[E] <: [E_1] \vee [E] <: [E_3]}$$

```
1 $expr ? $b : $c; // typeOf(E) is subtypeOf($b) or subtypeOf($c)
2 $expr ? : $c; // typeOf(E) is subtypeOf($expr) or subtypeOf($c)
```

Listing 4.2: Ternary

Assignments with operators (1) always resulting in ints

$$\begin{aligned} E_1 \&= E_2 \\ E_1 \mid &= E_2 \\ E_1 \wedge &= E_2 \\ E_1 << &= E_2 \\ E_1 >> &= E_2 \\ E_1 \% &= E_2 \end{aligned}$$

$$\frac{}{[E_1] = integer()}$$

```

1 $a &= $b; /* $a = integer() */
2 $a |= $b; /* $a = integer() */
3 $a ^= $b; /* $a = integer() */
4 $a <=<= $b; /* $a = integer() */
5 $a >>= $b; /* $a = integer() */
6 $a %= $b; /* $a = integer() */

```

Listing 4.3: Assignments with operators (1)

Assignments with operators (2) string concat (.=)

$$\frac{E_1 .= E_2}{[E_1] = \text{string()},}$$

$$\text{if}([E_2] <: \text{object}()) \Rightarrow \text{hasMethod}([E_2], \text{"__toString"})$$

```

1 $a .= $b; /* $a = string() */
2 // An error occurs when $b is of type object() and
3 // __toString is not defined or does not return a string

```

Listing 4.4: Assignments with operators (2)

Assignments with operators (3) resulting in int where rhs is no array

$$\frac{E_1 /= E_2}{[E_1] = \text{integer()},}$$

$$\frac{E_1 -= E_2}{[E_1] \neq \text{array}(\text{any}())}$$

```

1 $a /= $b; /* $a = integer() */
2 $a -= $b; /* $a = integer() */
3 // An error occurs when $b is of type array() for /= and -=
4 // Fatal error: Unsupported operand types

```

Parameters

Parameters in class instantiation

*These parameters are just examples for what happens if they have typeHints (*th*), default values(*v*) or none *The constructor can be found in the m3 model (@constructors(loc classDecl, loc constructorMethodDecl))

$$\frac{\text{new } C_1 (A_1, A_2, \dots, A_k) \subseteq \Gamma \quad \text{class } C (th_1 P_1, P_2 = v, \dots, P_k) \subseteq \Gamma}{\text{\$a} \rightarrow m() (A_1, A_2, \dots, A_k) \subseteq \Gamma \quad \text{public function } m() (th_1 P_1, P_2 = v, \dots, P_k) \subseteq \Gamma}$$

$$\frac{\text{function}_1 (A_1, A_2, \dots, A_k) \subseteq \Gamma \quad \text{function } (th_1 P_1, P_2 = v, \dots, P_k) \subseteq \Gamma}{[P_1] <: [A_1], [A_1] <: [th_1], [P_1] <: [th_1], \text{hasRequiredParam}(P_1), \text{hasRequiredParam}(P_k)}$$

```
1 new C($foo);
```

Listing 4.25: Parameters in class instantiation

Scope

Type of a certain variable within some scope

this applies to global- class- function- and method- scope

$$\frac{E, E', E'', E''' \dots \text{etc} \subseteq f \quad E \text{ is a variable}}{[E] = [E] \vee [E'] \vee [E''] \vee [E'''] \dots \text{etc}}$$

```
1 function f() {
2     $a = 1;
3     $a = "true";
4 }
5 // typeof($a) is typeof($a1, $a2, ..., $an);
```

Listing 4.26: Type of a certain variable within some scope

Return type of function or method (1) having no return statements or return;

$$\frac{\text{return} \not\subseteq f \vee \text{return}; \subseteq f}{[f] = \text{null}() }$$

```

1 function f() {} // no return = null()
2 function f() { return; } // return; = null()

```

Listing 4.27: Return type of function or method (1)

Return type of function or method (2) every exit path ends with a return statement

$$\frac{(\text{return } E_1) \vee (\text{return } E_2) \vee \dots \vee (\text{return } E_k) \subseteq f}{[f] <: [E_1] \vee [E_2] \vee \dots \vee [E_k]}$$

```

1 function f() {
2   if (rand(0,1))
3     return $a;
4   else
5     return $b;
6 }
7 // returns typeof($a) or typeof($b)

```

Listing 4.28: Return type of function or method (2)

Return type of function or method (3) possible no return value

$$\frac{(\text{return } E_1) \vee (\text{return } E_2) \vee \dots \vee (\text{return } E_k) \vee (\neg \text{return}) \subseteq f}{[f] <: [E_1] \vee [E_2] \vee \dots \vee [E_k] \vee \text{null}()}$$

```

1 function f() {
2   if (rand(0,1))
3     return $a;
4   else if (rand(0,1))
5     return $b;
6 }
7 // returns typeof($a) or typeof($b) or null()

```

Listing 4.29: Return type of function or method (3)

Function calls

Function call

$$\frac{f() \subseteq \Gamma}{[f()] <: \text{return of } [f]}$$

```

1 function f() {}
2 f();

```

Listing 4.30: Function call

Function call variable

$$\frac{E \equiv E_1() \subseteq \Gamma}{[E] = \text{any}(),}$$

$$[E_1] <: \text{object}() \vee [E_1] = \text{string}(),$$

$$\text{if}([E_1] <: \text{object}()) \Rightarrow \text{hasMethod}(\text{"__invoke"})$$

```

1 function f() {}
2 $f = "f";
3 $f(); // unknown what function will be called
4 // [$f] <: object(with __invoke method) | [$f] = string()

```

Listing 4.31: Function call variable

How to resolve expressions:

- Find all expressions which are defined above and annotate them with @type.
- Annotate the rest of the expressions with @type = any(); (should only be for relevant expressions)

4.3 Constraint solving

When we have all the constraints from the source code as facts, we will solve the constraints until we can no longer solve any constraints. The result will be a list of possible types for each class, method, fields, functions, variable and expression. The first step is to initialise all type-able objects. In this initial phase the types of each object is of type any, except for the literal types which can be resolved already. When we solve the constraints step by step, we will be able to limit the number of possible types for a certain object. We do this by taking the intersection of the constraint result and the possible types we have. This way there should be less and less possible types for each variable.

When we take the intersection of none overlapping types, we have a type error. There is no possible type for this object, resulting in an empty set of possible types.

The algorithm In algorithm 2 we show the algorithm to solve the constraints. The algorithm input is a set of constraints and the output is a map of solutions. The set of constraints are the constraints defined in constraint extracting section, and the map of results is the location of all type-able objects with their possible solutions. The init function on line 1 adds all type-able objects to the set of possible solutions. The initial possible types of the objects will be the collection of all possible types, called *Universe()*. Only the literal types can be resolved already, like strings, numbers and boolean constants.

Line starts a loop until a fixed point is reached. In Rascal this method is called Solve() and will loop until there are no more changes in the given data. The methods of line 3-4 may alter the values of constraints or solutions.

The first function of the loop on line 3, *deriveMore*, visits all constraints and checks if there can be new constraints extracted based on the latest constraints and solutions. Example of these new constraints are conditional constraints, which could only be added if more information of the conditional was available.

Function *propagateSolutions* on line 4 propagates resolved estimates. Here we take the intersection of the known solutions with the given constraints.

Algorithm 2: Constraint solving algorithm

Input: set[Constraint] constraints

Output: map[TypeOf expression, set[Type] possibleTypes] solutions

```
1 map[TypeOf, set[Type]] solutions = init(constraints);
2 while changes in constraints or solutions do
3   | constraints = constraints + deriveMore(constraints, solutions);
4   | solutions = propagateSolutions(constraints, solutions);
5 end
6 return solutions;
```

4.4 Annotations

After we gathers all the facts from the source code, we will add additional information which we read from the annotations. For this we use regex to match @return type and @param type var for methods and functions. We read @var type for variables and class attributes. In our first analysis we do not include the facts we gathered from the annotations. In the second analysis we do include the facts. This way we can compare the end results.

In order to gain some knowledge about the reliability of the annotations, we compare the result our or initial analysis with the provided provided annotation information. Here the implementation should comply to the used annotations.

Chapter 5

Analysis

In order to validate the performed research we have tested them on the most popular packages of Packagist¹, which are listed in table 5.1. The statistics are generated using phploc². All packages have between 2 and 6 million downloads. Packagist is a repository for Composer³ projects. Composer is a dependency manager for PHP projects. All external plugins for PHP projects can be managed via a composer.json file. You only need know the name and a version of the external package in the repository of your project.

*This is a list of the 30 most popular packages of packagist ordered by total lines of code, in July 2014.

¹ = Directories, ² = Files, ³ = Classes, ⁴ = Interfaces, ⁵ = Traits, ⁶ = Not in class or function

Table 5.1: List of analysed projects.

To collect the source code for each project, we have executed the following steps:

1. `git clone` the github repo.

¹<https://packagist.org/explore/popular>, July 2014

²<https://github.com/sebastianbergmann/phploc>, July 2014

³<https://getcomposer.org/>, July 2014

2. Run `composer install`, and the source code including dependencies will be downloaded in the `/vendor` folder.
3. Remove the `autoload.php` and `composer` folder, as we don't need them.
4. Remove the test folders by removing all folders matching `Tests` or `tests`.

To measure the coverage:

1. `git clone` the github repo.
2. Run `composer install`, and the source code including dependencies will be downloaded in the `/vendor` folder.
3. Run the unittests and use `xdebug` to resolve the types.
4. Compare the results.

Chapter 6

Results

The results below are based on our analysis on PhpStorm. The first table contains information about the source folder of the test projects. The second table includes vendor folders, which makes it harder to pin point the problems, but does give a better indication of the impact of using annotations. In either cases the vendor folders are used in the analysis to resolve types. The type resolution is based on the type inference implementation of PhpStorm.

Table 6.2: Results of type usage, including vendor folder

6.2 Validation of the results

Say something about:

- Soundness (what we measured, is it correct?)
- Completeness (how much did we measure?)
- Accuracy (how precise are the results?)

6.3 Annotations

The results of the analysis when adding the annotations to the analysis. Compare the results with the results of the analysis without the annotation information.

Chapter 7

Case Study

Explain how the case study is performed.

This chapter will show the case study, but I just need to place this information somewhere.

A list of the 40 most popular packages from packages.

- create composer file
- composer install
- mkdir phploc
- list all packages: `find ./vendor/* -maxdepth 1 -mindepth 1 -type d -exec ls -d ""`
- prefix the list with "phploc" and postfix with " > phploc/<file>.phploc"

Chapter 8

Conclusion

Summary of the whole work, with conclusions. T.B.A.

8.1 Conclusion

8.2 Future work

These items will not be covered by the analysis (maybe add this to threats/future work)

- Analysis is flow insensitive
- Closure
- References
- Variable constructs (variable -variable, -method/function calls, -class instantiation, eval) :: todo: explain WHY not.
- Yields

Explain something about combining this analysis to other analysis (like dead code elimination, constant folding/propagation resolve, alias analysis, array analysis) to gain more precise results.

Something about performance optimisations... Explain what is already done to boost the performance and what still can be done.

Use a bigger corpus to gains better results of the analysis by doing analysis on more programs.

8.3 Threats to validity

When relying on annotations for analysis, the annotations need to be correct and sound. The hard part is that the annotations are not examined on runtime, and are therefor not easily validated.

Glossary

AST

An abstract representation of the structure of the source code. .

PSR

PHP Standard Recommendation (PSR) is project which provides rules for commonalities between PHP projects. Autoloading, coding style guide, logging, and HTTP Message interface are the first few accepted standards. The PHPDoc standard describes how and what to use in doc blocks and is currently in draft phase. See <http://www.php-fig.org/> for more information. .

Rascal

Rascal is a meta-programming language developed by SWAT (Software analyse and transformation) team at CWI in the Netherlands. See <http://www.rascal-mpl.org/> for more information.

reflexive transitive closure

A relation is transitive if $\langle a, b \rangle \in R$ then $\langle b, a \rangle \in R$.

A relation is reflexive if $\langle a, b \rangle \in R$ and $\langle b, c \rangle \in R$ then $\langle a, c \rangle \in R$.

A reflexive transitive closure can be established by creating direct paths for all indirect paths and adding self references, until a fixed point is reached.

stdClass

A predefined class in the PHP library. The class is the root of the class hierarchy. It is comparable to the Object class in Java.
